CHAPTER HIGHLIGHTS

- Why research matters
- Humans as limited information processors
- Heuristics (representativeness and availability)
- Shermer’s (1997) categories of how thinking goes wrong:
  - Problems in scientific thinking
  - Problems in pseudoscientific thinking
  - Logical problems in thinking
  - Psychological problems in thinking
- The role of commonsense in posing research questions
- The difference between a law, a theory, and a hypothesis
- What makes something a good research question?

WHY RESEARCH MATTERS

In the movie *The Big Short*, which depicted the implosion of the housing market and the collapse of the financial system in the United States, hedge-fund manager Mark Baum (the character played by actor Steve Carell) and his team go out in the field to collect data...
on the “health” of the housing market. Rather than accepting someone else’s conclusion that the housing market was a “bubble” about to burst, they collect their own data by consulting a real estate agent, several mortgage brokers, and even an exotic dancer (who has adjustable rate mortgages on five houses, as it turns out). Social scientists might not consider this credible research, but at least Baum and his team were willing to look at some evidence. As you will learn later in this book, there were some problems with their approach, although their conclusion was correct (it wouldn’t have made a good story, otherwise). As we will see in Chapter 9, their sampling strategy was flawed because they looked at only one housing market in the United States (Miami); they needed a random sample of housing markets across the United States to be more certain about the housing bubble.

Every day you see behavior that triggers questions ranging from the mundane—“What do people think of students who wear pajamas to class?”—to the more important—“Do people disclose less information to their health-care providers when a ‘medical scribe’ (i.e., someone taking notes for the physician) is in the room?” How do we evaluate the research in terms of its credibility? That is, what makes research believable or convincing? What criteria should we use in evaluating the findings of a research study? Courses in research methods provide the tools to evaluate research. Students may take research methods because it is required, but the information will serve them far beyond the course. Learning how to evaluate research may help students make more informed and potentially life-altering decisions in the future (e.g., whether to take a particular medication to treat a condition or how much to pay for a particular home).

Research can help you answer a variety of questions, some of them very important. Being able to evaluate research gives you a powerful set of tools to solve problems, especially because the body of knowledge is expanding exponentially. To ask and answer good questions, it is helpful to understand how humans think because we humans have cognitive capacities that both help (category formation; commonsense; flexibility; creativity) and hurt (stereotypes; heuristics, that is shortcuts in thinking) the research process. In fact, the same cognitive capacity can be adaptive in some situations and maladaptive in others. For example, using speed to make a decision under duress might save your life, but it might make you an unreliable eyewitness. Recognizing these cognitive characteristics in yourself will help you maximize the positive aspects and minimize the negative aspects in the research process. In this chapter, you will learn about the kinds of heuristics or shortcuts we use in thinking and how these may shape our approach to research. Armed with this information, you will be better prepared to both evaluate the research that others conduct and carry out your own research.

In this chapter, four categories of how thinking “goes wrong” from a list generated by Michael Shermer (1997) will be highlighted. We will also look at some adaptive...
characteristics humans have, most notably, commonsense. The chapter also introduces you to the distinctions between law, theory, and hypothesis (a proposed explanation for the relationship between variables that must be tested) and explores how a good research question is connected to theory.

THE RESEARCH PROCESS: HUMANS MAKE PREDICTIONS

Humans are limited information processors; what this characteristic means is that we cannot process all incoming information at once. As a consequence, we learn to focus on the most important features of an object (or situation). An important consequence of this limitation is that we are forced to make predictions. Predictions are the essence of research: we make hypotheses (proposed explanations about the relationships of variables we want to test). If you see traffic lined up along an artery where traffic usually flows smoothly, you likely conclude there is some kind of traffic tie-up.

This limited ability to process information has some important effects on how we organize material (and think about research). To manage the overload of information around us, humans evolved to chunk or categorize information into groupings or clusters. This kind of organization leads us to form overarching categories; we have words that designate those categories, like vegetable or sports or furniture. A term that is often used to describe such mental representations of knowledge is a schema. If we have a schema for something, we understand its gist or essence; a schema serves as a generalized description of the core characteristics of a given role, object, or event. We might have a schema for a role (e.g., father), for an object (e.g., a chair), or for an event (e.g., going to a restaurant). The benefit of having a schema is that it provides a condensed version of the information that is available about an entity in the world and it helps us make predictions.

Our ability to compartmentalize by categories minimizes the cognitive load and leaves our brains available to respond to incoming information that may have implications for survival (a car speeding toward us; a loud noise). That’s the upside. The downside is that such compartmentalization leads to stereotypes and overgeneralizations, which can interfere with thinking objectively about research. Redheads are tempestuous, people who live in Detroit drive American-made cars, New Yorkers like to wear black, and so on. Our propensity for categorization may lead us to minimize the differences across dimensions and to categorize stimuli as similar when, in fact, there may be important differences.

Hypothesis: "A testable proposition based on theory, stating an expected empirical outcome resulting from specific observable conditions" (Corsini, 2002, p. 463).

Schema: mental representation of a category that can be a role, an object, or an event (e.g., parent, table, or going to the dentist, respectively).
HEURISTICS AND THE WORK OF KAHNEMAN AND TVERSKY

We have discussed some advantages and disadvantages to the formation of schemas. Let’s talk about some other cognitive characteristics of humans and how they interact with the research process. In particular, we will focus on what are known as cognitive heuristics or mental shortcuts and how they both shape research questions and the answers participants provide.

The researchers Daniel Kahneman and Amos Tversky (see, for example, Kahneman & Tversky, 1972, 1973, 1979; Tversky & Kahneman, 1971, 1973, 1974) studied these predictive tendencies (heuristics) or shortcuts in thinking. Kahneman received the Nobel Prize in Economics (psychologists like to claim him as one of their own) for the work he and Tversky did on these cognitive biases. (Nobel prizes are awarded only to living recipients, and Tversky had died by the time the work was honored.)

We can comprehend the evolutionary value in being an animal that operates on incomplete information and the ability to use schemas for prediction. The work of Kahneman and Tversky focuses on these heuristics or shortcuts and illustrates how these shortcuts may lead us to incorrect decisions. Before you become discouraged about human capabilities, it’s useful to remember that the work of Kahneman and Tversky applies to particular kinds of decision-making problems, not to all problems. A good deal of their work focuses on the idea of representativeness (e.g., Kahneman & Tversky, 1972) and availability (e.g., Tversky & Kahneman, 1973), both of which have applications to the research process. Here the idea of representativeness is its frequency of occurrence in a population. It can also mean the extent to which an array of events or objects or people reflects the characteristics of its parent population (discussed in terms of sampling). Availability involves using examples that come easily to mind (e.g., because you just read an article on that topic).

The Representativeness Heuristic in Research

In one of Kahneman and Tversky’s classic examples, participants were presented with the following: “All families of six children in a city were surveyed. In 72 families the exact order of births of boys and girls was GBGBBG. What is your estimate of the number of families surveyed in which the exact order of births was BGBBBB?” (Kahneman & Tversky, 1972, p. 432). Not surprisingly, a significant number of the respondents (75 of 92) said the second option was less likely to occur because, as Kahneman and Tversky argued, it seems less representative of the population. When the question is posed in terms of the frequency with which two birth sequences occur (BBBBGG vs. GBBGBG), the same participants pick the second sequence. The first looks “fixed” or nonrandom to us (and them). How representative something looks is one heuristic or bias that may influence the research process. We might select a stimulus (e.g., photograph) as representative of a population of interest (e.g., recreational areas with camp sites) without knowing the full range of existing...
sites (compare Figure 1.1 and Figure 1.2), particularly in different geographical regions. If we try to generalize from a limited range of pictures to say something definitive about people’s evaluations of such settings, we might be overstating the results.

Although the work of Kahneman and Tversky focuses on the cognitive decision-making process (i.e., about the decisions we make, for example, about stimuli), the idea of representativeness emerges in other ways in research. You may be familiar with such phrases as “a representative sample” or “a randomly selected sample” (the example from *The Big Short* earlier in this chapter raised the issue of sampling; see Chapter 9 for a fuller discussion of sampling).

One central question in every research project is who the participants are and to what extent the results of the study are therefore “representative” of the population of interest. If we do research using a participant pool that consists of students enrolled in an introductory psychology course, we can ask several questions about who participates, starting with the degree to which people who take an introductory course in psychology are representative of that student body as a whole (by gender, race, income, and many other qualities). Every decision we make about securing participants (e.g., the time of day we run the study) is likely to influence the representativeness of our sample and, in turn, of our results.

**The Availability Heuristic in Research**

Let’s now turn to the availability heuristic, the second heuristic from Kahneman and Tversky to be discussed. The availability heuristic suggests that we make decisions to some extent based on how easy it is for us to think of examples from that domain. One well-known example of Kahneman and Tversky’s work on availability involves the judgment of word frequency (Tversky & Kahneman, 1973). Take the letter K. Question:...
In words with three or more letters in English text, does the letter K appear more frequently in the first or third position?

When we hear this question about the letter K, what happens? We start to generate words that BEGIN with the letter K because it is available to us. That seems easier to do than to think of words with K in the third position. But, after you’ve run out of key, knife, knight, and knit, you begin to realize that, well, bake, cake, fake, lake, make, rake, take, bike, hike, like, mike, . . . (k in the third position) generates far more possibilities; in fact, two times as many in a typical text (Tversky & Kahneman, 1973).

The availability heuristic emerges in research in many ways. For example, if we develop a questionnaire that first asks people to rate a list of items, for example, what they like about their university (e.g., food, school spirit, academics, career counseling, cost, and residence halls), and then we ask them an open-ended question about advantages and disadvantages of attending that university, the items from that initial list will be AVAILABLE in memory and will likely influence what people say in the open-ended question. If we had asked the open-ended question first, we might get a different set of responses. Thus, the order in which information is presented to participants may influence their responses and is related to the availability heuristic. Chapter 8 discusses one way to address this
problem of availability by doing what is known as **counterbalancing** the order of presentation of materials. In complete counterbalancing, all possible orders of presenting the materials are included in the research approach.

### Humans Want to Confirm Hypotheses

What we have available in memory influences us in other important ways, specifically when we think about ways to confirm our hypotheses rather than when we think of ways to disconfirm them. Figure 1.3 shows a well-known example of our preference for thinking about information in terms of the way it is presented: the **Wason Selection Task** (1966, 1968). This task involves making decisions about two-sided cards. This task has many variations, but in one version (Figure 1.3), people are told the following: These cards have two sides: a letter of the alphabet on one side and a number on the other. Then people are told a “rule,” and their job is to make sure the rule is being followed. Here is the rule: If there's a vowel on one side, there's an even number on the other.

Then they are asked:

Which card or cards do you have to turn over to make sure the rule is being followed?

![FIGURE 1.3 Example of Wason Selection Task](image)

**Try This Now**

Before You Read Further, what card(s) did you select? People usually select E and frequently E in combination with K and 4; they hardly ever select 7.

Why? One reason is that people heard the statement, “If there's a vowel. . . .,” and so what do they see? They see a vowel (E). They have a vowel available (think availability heuristic), and it seems logical to investigate the other side of that card. And they are correct, at least to that point; they should turn over the E. But they must also turn over the 7 to make sure that there is no vowel on the other side of that card. People don‘t do that; they don’t think to disconfirm the rule.

The Wason Selection Task demonstrates an important part of thinking related to research. Humans have a much easier time thinking of ways to confirm information (think hypotheses) than to disconfirm it. What comes far less easily is taking a disconfirmational strategy to the hypothesis or the theory by seeking to disconfirm it. In research,
we seem far more willing to seek to confirm rather than to disconfirm. We tend to exhibit what is known as confirmation bias in that we look for information that confirms our hypotheses. We also need to ask ourselves the question, what situation(s) would be a good test to show that the hypothesis is incorrect?

In the research findings of Kahneman and Tversky, we have already discussed that our cognitive processes are susceptible to a wide range of influences and biases. Even such respected researchers as Kahneman and Tversky may have been susceptible to the biases they studied. In the article “Voodoo Correlations Are Everywhere—Not Only in Neuroscience,” Klaus Fiedler (2011) showed that the use of the letter K (discussed earlier in this chapter) for Tversky and Kahneman’s (1973) demonstration of the availability heuristic may have used an unrepresentative letter (K). Because this finding has not been replicated with many other letters of the alphabet [as Fiedler reported, citing the work of Sedlmeier, Hertwig, and Gigerenzer (1998)], using K may not have been a good test of Tversky and Kahneman’s hypothesis. In selecting their stimulus (K) intuitively, Fiedler explained, Tversky and Kahneman were fallible human beings: “Such an intuitive selection process will typically favor those stimuli that happen to bring about the expected phenomenon, making mental simulation an omnipresent source of bias in behavioral research” (Fiedler, 2011, p. 165).

In other words, Fiedler (2011) argued that the authors (consciously or otherwise) selected a stimulus that was likely to prove their point. The larger message of this research example provides a cautionary tale: As researchers and cognitive animals, we want to validate our hypotheses; by reinforcing what the Wason Selection Task shows, we seek to prove, not to disprove, and we are likely to select stimuli that support our hypotheses rather than stimuli that challenge or refute them.

How can we guard against this common “affirming” behavior? Being aware that we are likely to make these errors is the first step. Asking how we might disprove or refute the hypothesis is another step. Imagining the conditions under which a prediction would not hold is as important as identifying the conditions under which the prediction is likely to hold. In other words, we need to ask ourselves what evidence would counter the hypothesis.

### REVISIT AND RESPOND

At this point, you should be able to:

- Explain what it means to say humans are limited information processors
- Describe the concept of a schema and its adaptive and maladaptive implications for research
- Define heuristics and give examples of representativeness and availability
- Explain the Wason Selection Task and what it shows about the difference between confirming and disconfirming hypotheses
### TABLE 1.1 Twenty-Five Fallacies That Derail Thinking

<table>
<thead>
<tr>
<th>Category</th>
<th>Fallacy Description</th>
</tr>
</thead>
</table>
| “Problems in scientific thinking” (pp. 46–48) | 1. Theory influences observations  
2. The observer changes the observed  
3. Equipment constructs results |
| “Problems in pseudoscientific thinking” (pp. 48–55) | 4. Anecdotes do not make a science (stories recounted in support of a claim)  
5. Scientific language does not make a science (watch out for jargon)  
6. Bold statements do not make claims true  
7. Heresy does not equal correctness (belief/opinion contrary to religious doctrine)  
8. Burden of proof—convince others of validity of evidence (not of mere existence of evidence)  
9. Rumors do not make reality  
10. Unexplained is not inexplicable  
11. Failures are rationalized (pay attention to negative findings)  
12. After-the-fact reasoning (correlations do not mean causation) |
| “Logical Problems in Thinking” (pp. 55–58) | 13. Coincidence (gambler’s fallacy)  
14. Representativeness (base rate)  
15. Emotive words and false analogies (not proof; merely tools of rhetoric)  
16. *Ad ignorantiam*—an appeal to ignorance; belief should come from positive evidence in support of a claim, not from lack of evidence for or against a claim  
17. *Ad hominem* (to the man) and *tu quoque* (you also)—watch that you focus on the content, not on the character of the person making the argument or on the consistency of the behavior of the person relative to the argument the person is making  
18. Hasty generalization—prejudice/improper induction; conclusions before facts warrant it  
19. Overreliance on authorities (false positive: accept results just because supported by someone admired; false negative: reject results just because supported by someone you disrespect)  
20. Either-or—fallacy of negation or the false dilemma (creation vs. evolution); dichotomizing the world, such that if you reject one position, you are forced to accept the other  
21. Circular reasoning—begging the question; tautology  
22. *Reductio ad absurdum* and the slippery slope—refutation of an argument by carrying the argument to its logical end and so reducing it to an absurd conclusion |
| “Psychological Problems in Thinking” (pp. 58–61) | 23. Effort inadequacies and the need for certainty, control, and simplicity (have to practice thinking logically and clearly; thinking is skilled work)  
24. Problem-solving inadequacies—we don’t seek evidence to disprove  
25. Ideological immunity, or the Planck problem—we all resist paradigm change; opponents have to die out gradually; we build up immunity against new ideas; the higher the IQ, the greater the potential for ideological immunity |

Source: Adapted from Shermer, 1997, pp. 44–61.
OTHER PROBLEMS IN THINKING

We have discussed several problems in thinking; let’s discuss a few more and in the process reinforce some of the information we have covered. In Shermer’s (1997) *Why People Believe Weird Things*, Chapter 3 is titled “How Thinking Goes Wrong: Twenty-Five Fallacies That Lead Us to Believe Weird Things.” In that chapter, Shermer discussed four major categories of difficulties in how we think about evidence and data (Table 1.1). To illustrate the categories and the problems they present for our research, we will focus on examples (see shading) in each category.

**Problems in Scientific Thinking: Theory Influences Observations**

As part of the category “Problems in Scientific Thinking,” Shermer listed “Theory influences observations” (1997, p. 46). What this statement means for us is that theory in some sense directs, shapes, or may even limit the kinds of observations we make. Again, we see that we might limit ourselves because we look for a particular kind of behavior rather than being open to any kind of activity in the environment. Most people have never heard a peacock’s scream and would never guess that the sound they hear when visiting a suburb outside Los Angeles comes from that bird. Why? Because most of us think peacocks are birds that reside in captivity. But peacocks have roamed wild in some places (like Rolling Hills on the Palos Verdes Peninsula in California) for more than 100 years. We limit our choices to the most likely suspects. As Shermer stated, “[O]ur perceptions of reality are influenced by the theories framing our examination of it” (p. 46).

**Problems in Pseudoscientific Thinking: Scientific Language Does Not Make a Science**

Pseudoscientific thinking involves reference to a theory or method that is without scientific support. What we are thinking about may be called science, but it may have no scientific basis, and it is not based on the scientific method. Shermer notes, “Scientific language does not make a science” (p. 49). It is tempting to use words that sound impressive and appear in a discipline, even when no convincing explanation of their meaning or importance is provided. What’s better than coming up with a new term, especially with your name linked to it? Social science is replete with such terms. The use of scientific terms is not necessarily incorrect, but what is a problem is the use of terms without an explanation of their meaning in everyday language.

Furthermore, using such words without supporting evidence and confirmation is an example of pseudoscientific thinking. In the area of health-care research, for example,
many architects now use the term *evidence-based design* to describe their work. Without a clear understanding of what that term means, and what qualifies as credible evidence (e.g., subjective measures such as patients’ self-reports? Objective measures such as vital signs, levels of pain medication, and recovery time?), simply using that phrase makes designers sound more authoritative than they actually are. The use of a term in a discipline without an explanation of its meaning or clear indication of how the term is operationalized (i.e., how it is being measured) creates misunderstanding.

**COINCIDENCE (GAMBLER’S FALLACY) AND REPRESENTATIVENESS (BASE RATE)** Two other important aspects of this category “Problems in Pseudoscientific Thinking” according to Shermer (1997) are *coincidence (gambler’s fallacy)* (pp. 53–54) and *representativeness (base rate)* (pp. 54–55). These two aspects frequently appear when we make assumptions in the research process. In the gambler’s fallacy, we commit a logical fallacy and lose sight of the facts of probability; we think an event is less likely to occur if it has just occurred or that it is likely to occur if it hasn’t for a while. When we toss a coin, we have a 50–50 chance of heads. Each toss of the coin is an independent event. Yet if we have seen three heads in a row, we may be very likely to predict that the next toss will yield tails when, in fact, the odds of a tail (or head) appearing on the next coin toss is still 50–50.

A related idea is the mistaken belief that correlation (for example, of two co-occurring events) is causation. Superstitions are an example of this erroneous thought process. Athletes are notorious for superstitions (Vyse, 1997). For example, if you win two games in a row in which you tie your left shoelace first as you prepared for the game, you may believe that tying that left shoe first influenced the victories. These two events (left shoe tying and game victory) are correlated, that is, when one event happened the other also happened, but shoe tying did not achieve the victory. We are pattern seekers because we are limited information processors. We look for causal relationships that may not exist; we see patterns (a series of coins coming up heads) and predict that the next coin toss will produce a tail. We make this prediction because such an outcome would be more representative of the occurrence of events as we know them. This is an aspect of representativeness (which we discussed earlier in the chapter).

In representativeness, we are on the lookout for events in the world that match or resemble the frequency of occurrence of those events in our experience. When we encounter a situation that does not look representative, we are likely to ignore, disregard, or mistrust it. As we have already discussed in this chapter, Kahneman and Tversky’s work is full of examples of problems in thinking related to representativeness. The base rate is the frequency with which an event (e.g., twins, a hole in one, or perfect SATs) occurs in a population. We may have little knowledge of the actual base rate of events in a population, and we often overestimate the occurrence of events (e.g., likelihood of a plane crash or

---

**Coincidence (gambler’s fallacy):** thinking that an event is less likely to occur if it has just occurred or that it is likely to occur if it hasn’t occurred for some time (e.g., assuming a slot machine will pay off because it hasn’t for the past few hours).

**Representativeness (base rate):** one of the heuristics talked about by Kahneman and Tversky (1972) in which we make decisions based on how representative or characteristic of a particular pattern of events data are (e.g., people think the birth order BGBBGG is more representative of a sequence of births than is BBBGGG).
likelihood of winning the lottery). Our overestimation of the base rate may be influenced by the availability heuristic (discussed earlier in the chapter). If we have read or heard about a recent plane crash, for example, we are more likely to overestimate the occurrence of a plane crash for our upcoming trip.

The odds of dying from a motor vehicle accident are far greater than the odds of dying from a commercial airline accident. Likewise, we are far, far more likely to die from heart disease than we are from homicide (Kluger, 2006). In other words, we are not logic machines, and we don’t carry around statistics in our heads; instead we carry estimates of events based on the frequency with which we have encountered them, and exposure to media typically elevates our estimates of the base rate, or the frequency with which events actually occur.

These errors in understanding the base rate underscore the importance in research of assessing the degree to which participants in your study may have familiarity with the topics under investigation. For example, if you were evaluating patients’ reactions to hospitalization, you would certainly want to ask a question about the number of prior hospitalizations. You want to ask yourself what aspects of a participant’s background might have relevance and possibly influence your research. As another example, if you were investigating students’ satisfaction with their educational institution, it might be helpful to know if the college they attend was their first choice.

Try This Now

What kinds of background variables and experiences might influence students’ satisfaction with their educational institution, aside from qualities of the institution itself?

Logical Problems in Thinking: Hasty Generalization and Overreliance on Authorities

Among the logical problems in thinking that Shermer lists, he gives us “hasty generalization” (p. 56)—reaching conclusions before the evidence warrants—or faulty induction. Induction is reasoning from premises to a probable conclusion. In faulty induction, the conclusion is not warranted. People also describe this kind of thinking as stereotyping. As but one example, when we take a limited range of evidence about an individual and ascribe those qualities to the group of which the person is a member, we are stereotyping. A popular television show,1 The Big Bang Theory, has characters that embody stereotypes, whether

---

1Ranked seventh in prime broadcast network television shows in the United States the week of June 1, 2015, according to Nielsen (http://www.nielsen.com/us/en/top10s.html).
Sheldon Cooper, the brilliant but interpersonally less skilled theoretical physicist, or Amy Farrah Fowler, his “girlfriend” (those who faithfully watch the show will recall that initially Sheldon describes Amy as a “girl” and his “friend” but not his “girlfriend” in the traditional meaning of the term). For long-term watchers of the show, the staying power of the series comes through the evolution of these characters over time as they become less true to the stereotype they represent. But many individuals argue that the portrayal of these characters reinforces unfortunate and hurtful stereotypes about scientists and gender (Egan, 2015).

Hasty generalizations are a problem in many steps of the research process. We can consider the problem of hasty generalization when we talk about how much data are needed before conclusions are warranted. We can also include hasty generalization when we talk about sampling (see Chapter 9). Because humans are limited information processors and pattern seekers, we are eager to take information and package or categorize it; this process makes the information more manageable for us, but it may lead to errors in thinking.

A second kind of logical problem in thinking that Shermer lists is “overreliance on authorities” (pp. 56–57). In many cases, we accept the word or evidence provided by someone we admire without carefully examining the data. In the domain of research, we may have an overreliance on the published word; that is, we assume that when we read a published article, we should unquestioningly accept its data. Unfortunately, as we increasingly observe in academia, we should be far more skeptical about what has been published. Instances of fraud are numerous. Consider the relatively recent case of fraud involving a graduate student, Michael LaCour (and Donald Green, the apparently unknowing faculty mentor), who published work in *Science* (LaCour & Green, 2014) showing that people’s opinions about same-sex marriage could be changed by brief conversations (http://retractionwatch.com/2015/05/20/author-retrench-study-of-changing-minds-on-same-sex-marriage-after-colleague-admits-data-were-faked/). LaCour apparently fabricated the data that were the basis of his article, and the story of how this came to light reinforces the idea that findings must be reproducible. Two graduate students at the University of California–Berkeley are responsible for identifying the anomalies in LaCour’s data, which were revealed when these students from Berkeley tried to replicate the study. This revelation quickly led to the identification of other inconsistencies (e.g., the survey research firm that was supposed to have collected the data had not; no Qualtrics® file of the data was ever created).

The broader issue of reproducibility has been in the news recently with what is known as the Reproducibility Project (https://osf.io/ezcuj/), in which scientists are trying to reproduce the findings of 100 experimental and correlational articles in psychology published in three journals. The results (Open Science Collaboration, 2015) have been less than encouraging as many replications produced weaker findings than the original studies did. The authors emphasize that science needs both tradition (here reproducibility) as well as innovation to advance and “verify whether we know what we think we know.”

**Overreliance on authorities:** trusting authorities without examining the evidence.

**Qualtrics®:** online platform for survey research.

**Reproducibility Project:** project in which researchers are trying to reproduce the findings of 100 experimental and correlational articles in psychology.
Simply because an article has been published does not make it good science. Even well-known researchers publish articles that contribute little to the literature. In Chapter 2, we will see that we also need to take into account the standards of particular journals (e.g., their acceptance rates, scope of research they publish, and rigor of methodology) rather than treating the work in all journals as equal. Relying on authority without questioning the evidence leads to mistakes in repeating what might have been weak methodology, for example. As Julian Meltzoff (1998) stated in his useful book about critical thinking in reading research, we should approach the written (here published) word with skepticism and always ask, “show me.” Meltzoff went on to say, “Critical reading requires a mental set of a particular kind,” and he believed this mental set can be “taught, encouraged, and nurtured” (p. 8). The value of a particular argument has to be demonstrated with evidence that stands up to rigorous questioning. In regard to the research process, being willing to challenge authority by asking questions is an essential skill.

Psychological Problems in Thinking: Problem-Solving Inadequacy

The last category Shermer offered is “Psychological Problems in Thinking.” Among the problems identified is the idea that we exhibit “problem-solving inadequacy” (1997, p. 59) when we don’t seek evidence to disprove, only to confirm. We discussed this issue earlier in the context of the Wason Selection Task where people rarely thought that turning over the 7 was necessary. We invariably turn over the E (that is, look for evidence to confirm the hypothesis).

Consider the sobering evidence that “most doctors quickly come up with two or three possible diagnoses from the outset of meeting a patient. . . . All develop their hypotheses from a very incomplete body of information. To do this, doctors use shortcuts. These are called heuristics” (Groopman, 2007, p. 35). The word heuristics is familiar to us from material covered earlier in this chapter and, unfortunately, in the current context! Once we develop our hypotheses, we tend to stick with them; relinquishing them is difficult.

DOING SCIENCE AS TRADITION AND INNOVATION

When we think about how science advances, we can talk about the social and behavioral sciences broadly as a combination of tradition and innovation. As the work of Kahneman and Tversky (and others cited here) has shown, tradition is easier than innovation. It is much easier to operate within an existing framework and harder to figure out how to head in new directions. Most of the time we hope to master the tradition through a review of the literature, and then we take a small step toward innovation by figuring out how we can advance the discipline with this small step. We have to write a literature review or
summary of the work in the field that shows our knowledge of past work; at the same
time, we have to propose research that goes beyond the existing literature in some way.
We should be able to answer the question, “What’s new here?” If views to everyday nature
enhance recovery for surgical patients (Ulrich, 1984), why not see whether substitutes
for nature such as representational paintings of nature have beneficial effects such as pain
reduction. That use of “manufactured nature” would be a step forward. Researchers have
done this work, and such representational paintings of nature do in fact reduce stress
(Hathorn & Nanda, 2008; see Figure 1.4).

In your work, the problem of being governed by a paradigm or way of thinking about
a research topic directly affects the kinds of research questions you are willing to ask. Some
of the major changes in science have come from young researchers who perhaps were not
fully wedded to a single theory or methodology (that hypothesis itself might be testable).
As but one example, George Sperling’s (1960) doctoral thesis at Harvard University trans-
formed the way we think about the storage capacity of short-term visual memory by intro-
ducing the partial report technique. Prior to that time, using the whole report technique,
participants in research in visual memory storage had to call out or recall everything that
they had just seen in a brief exposure to visual stimuli. Sperling’s breakthrough was to have
participants call out information presented on only one row in the visual array of three rows
(Figure 1.5).
Sperling (1960) argued that to recall the information successfully from this one row, participants must have had all of the rows available at the time the particular row in question was cued. The cue was presented through an auditory tone (high, medium, or low) to correspond to the position of the rows of information on the page. This approach is a masterful example of tradition and innovation.

REVISIT AND RESPOND

At this point, you should be able to:

- Give an example from each one of Shermer’s (1997) categories:
  - Problems in scientific thinking
  - Problems in pseudoscientific thinking
  - Logical problems in thinking
  - Psychological problems in thinking
- Explain why science is a combination of tradition and innovation

RESEARCH AND THE VALUE OF COMMON SENSE

You might be a bit discouraged about how limitations in thinking affect the research process. There is reason for concern; on the other hand, humans have some remarkable cognitive assets.

In 1995, Marvin Minsky gave an address at Connecticut College at the dedication of its new interdisciplinary science center, funded by the Olin Foundation. His address was as wide ranging and stimulating as his research. Minsky is considered a founder of artificial intelligence, and one of his corporate affiliations was as a fellow of Walt Disney Imagineering (http://web.media.mit.edu/~minsky/minskybiog.html). Minsky died in 2016. Imagineers, as the name suggests, were part of a research and development think tank and worked on imagining ideas that might result in possibilities for entertainment (Remnick, 1997). In David Remnick’s article describing Disney Corporation’s view of amusement in the future, Minsky was reported to have accepted the offer to be an Imagineer because it “reminded him of the early days at the Artificial Intelligence Lab” (Remnick, 1997, p. 222). In describing his view of the future, Minsky said: “I’m telling you: all the money and the energy in this country will eventually be devoted to doing
things with your mind and your time” (p. 222). Speaking about what he thought future amusements might have in store, he said, “you’ll put on a suit and a special pair of glasses, and you’ll become involved in an experiential form of entertainment” (p. 222). Virtual reality and Google Glass®? This article was published almost 20 years ago.

Minsky was obsessed (not too strong a word) with the workings of the mind. Among Minsky’s many contributions, his book *The Society of Mind* (1985), written for a general audience, stands out because it provides a perspective on what makes the human mind amazing and distinctive. The book is presented as a series of short topics and reflects Minsky’s wide-ranging approach to discourse. Researchers often focus exclusively on the errors we make (Kahneman, 1991); in this book, Minsky also points out some of our cognitive assets, in particular, commonsense.

Discussing all of the processes that must be involved when making something with children’s blocks, Minsky stated, “In science, one can learn the most by studying what seems the least” (1985, p. 20). Furthermore, “What people vaguely call commonsense is actually more intricate than most of the technical expertise we admire” (1985, p. 72). Minsky argued it is easier to represent expertise than commonsense because with expertise you are dealing with a limited domain of knowledge; humans, on the other hand, bring to bear many different kinds of expert systems in solving the simplest of everyday problems. Hence, commonsense is anything but common, according to Minsky.

Much of what Minsky said can be applied to the research process. Research does not have to be sophisticated to be powerful; in fact, you could argue that the most powerful research is simple and elegant [think of Sperling’s (1960) partial report technique described earlier in this chapter]. People often complain that results in the social sciences are obvious, that is, we just demonstrate what everyone already knows—the we-knew-it-all-along effect, which is also called hindsight bias. But many such findings are not obvious until after you conduct the research. Commonsense may lead us to ask questions that have been overlooked. Don’t be afraid to ask questions that others would view as “obvious,” that is, as commonsensical. After research emerged showing that patients have positive judgments of therapists whose offices are neat but also personalized (Nasar & Devlin, 2011), a therapist is reported to have commented, “Isn’t that obvious?” If it were obvious, then why did so many therapists’ offices used in this series of studies fail to conform to these criteria?

**FLEXIBILITY IN THINKING**

Research is essentially about problem solving, and humans are very good problem solvers. In addition to commonsense, we can imagine objects used in a variety of ways. In essence,
seeing potential or flexibility is a form of creativity. This kind of problem-solving creativity we have as humans was described by Hubert Dreyfus (1972) when he said that humans don’t necessarily see the function of an object as fixed. Consider using a turkey baster to fill a sports car running low on transmission fluid or a door as a desk surface. The artist Marcel Duchamp used found objects, called readymades, as art; his bicycle wheel mounted upside down on a stool from 1913 is a well-known example. Nevertheless, we shouldn’t take this flexibility for granted, for either objects or processes. For example, we may apply the same process (procedure) when it is no longer appropriate to solve a problem. This is essentially a problem-solving set effect, meaning that we approach a problem using an established (repeated) procedure. In other words, we don’t recognize that there might be a more efficient way of solving the problem. This repeated procedural approach is a problem for researchers because we might settle in on a particular approach to evaluate a hypothesis because that is what other researchers have done (the tradition). We need to stop and ask ourselves how else we might go about investigating that particular issue. Can we improve on the tradition?

In the case of work on bias and discrimination, for example, researchers have been limited by using scales that directly ask questions about beliefs and attitudes. For example, an item from the Modern Sexism Scale is “It is rare to see women treated in a sexist manner on television” (Swim, Aikin, Hall, & Hunter, 1995). Participants who see such scale items are likely to self-monitor and answer with social desirability, presenting themselves in a good light (see Chapter 5 on measures).

A procedural breakthrough in addressing these kinds of problems with self-report measures has come in the form of Implicit Association Tests (IATs; Greenwald, Nosek, & Banaji, 2003), which use reaction time to measure people’s associations to topics (e.g., race, sex, obesity, and age) where your explicit response might be different than your implicit response (see https://implicit.harvard.edu/implicit/takeatest.html if you want to try out an IAT for yourself). If the pairing of “fat people” with the adjective “good” takes longer to react to than the pairing of “thin people” with the adjective “good,” then we, as well as the individual taking the IAT, have learned about whether the individual’s biases are congruent with the explicit positions that person expresses about weight. In all likelihood, if we had only explicitly asked about people’s attitudes toward people who are thin versus heavy, we would not see differences. Generally, people do not want to appear biased, in this case, against those in a particular weight category.

The challenge of research is to appreciate what previous studies have shown us (tradition) without becoming limited by them in the questions we can ask (innovation). But with experience, our thought processes become routinized, regularized, and less likely to see the new in the old, to think outside the box. All too soon we are unwilling to break out of the box. Are you up to the challenge?!
THEORIES: WHAT THEY ARE AND WHY THEY MATTER

We have spent a considerable amount of time talking about how information can be packaged in manageable ways to support the research process. There are three important terms that reflect different kinds of “packaging:” hypotheses, theories, and laws. In *The Dictionary of Psychology* (Corsini, 2002) a hypothesis is defined as “a testable proposition based on theory, stating an expected empirical outcome resulting from specific observable conditions” (p. 463). This dictionary defines a **theory** as “a body of interrelated principles and hypotheses that explain or predict a group of phenomena and have been largely verified by facts or data” (p. 994). A **law** is defined in this dictionary as “a theory accepted as correct, that has no significant rivals in accounting for the facts within its domain” (p. 536). Thus, a theory is the pivotal link between hypotheses, which are generated from theories at the least verified end of the spectrum, and laws, on the other end of the spectrum, which emerge when a theory is viewed as having been consistently verified and operates without challenge (Figure 1.6).

From a cognitive standpoint, theories are a way to organize and package information; they are a kind of compacting. Theories have superordinate points of view that allow predictions to be made; these are a kind of generalization from which specific predictions (hypotheses) emerge. These points of view need to be overarching, demonstrating their elasticity or applicability.

A question you might ask is whether the social and behavioral sciences have any laws. Three-and-a-half pages of laws are listed in Corsini’s (2002) dictionary, including the law of association, the law of belongingness, the law of common fate, the law of effect, the law of mass action, the law of proximity, and the law of vividness (pp. 537–540). These “laws” may conform to the idea of a theory being accepted as correct and lacking significant rivals, but many social scientists might have some difficulty easily coming up with an example of a “law” in their discipline. In contrast, we could all probably think of some of the laws of thermodynamics from high school; at the very least, we would know that there were laws of thermodynamics. Many of us think of laws as those referred to as natural laws, a “phenomenon of nature that has been proven to invariably occur whenever certain conditions exist or are met” ([http://dictionary.reference.com/browse/scientific+law](http://dictionary.reference.com/browse/scientific+law)).

As is evident in that definition, one challenge in the social and behavioral sciences is that human behavior doesn’t conform to this idea of invariable occurrence. As a result, in research, we spend most of our time testing hypotheses; if we are fortunate, these hypotheses are generated within the context of a theory. Thus, hypotheses and theories and their interrelationships are important to understand.
A theory, this pivotal concept, can be described as a set of principles or as an explanatory framework. In the social and behavioral sciences, theories use interrelated concepts to describe and predict behaviors (events) by making clear the relationships among variables. In Ulrich’s (1991) theory of supportive design, his explanatory framework, he offers three dimensions predicted to enhance patients’ well-being in health-care settings. These dimensions are (1) positive distraction, (2) social support, and (3) perceived control. Having (1) positive aspects of the environment (e.g., artwork, a view to nature, or music) to distract us from our worries; (2) the social contact of others, either in person (accommodated by seating) or by phone, e-mail, or Skype; and (3) the ability to control aspects of the environment around us, for example, by using the remote control or adjusting the temperature, is theorized to lead to greater well-being. These three constructs have in common their focus on the physical environment, on the one hand, and their predicted effect on human well-being, on the other. Could we imagine generating hypotheses within this theoretical framework? Before answering that question, let’s revisit the concept of a hypothesis, which is based on a theory, is testable, and states an expected empirical outcome based on observable data.

Try This Now
Come up with two hypotheses based on Ulrich’s (1991) theory of supportive design.

Theories are important because they help to organize and structure information and provide a way to think about ideas. Theories provide a structured foundation that should support the generation of hypotheses. At the same time, in returning to one of the themes of this chapter, it is important to recognize that biases may be embedded in theories. Shermer (1997, p. 46) quoted the physicist and Nobel laureate Werner Heisenberg who stated, “What we observe is not nature itself but nature exposed to our method of questioning.” In the case of Ulrich’s (1991) theory, for example, we may stop thinking of
other dimensions of supportive design if we accept his three-factor model. You can see that research questions are shaped by theory, and it is always a good idea to question whether the theory is limiting how you might think about the topic. In the case of Ulrich’s model, you might ask whether other aspects of design could be supportive beyond the three dimensions he identifies. For example, perhaps maintenance and upkeep need to be considered.

One other aspect of theories to appreciate is that they are powerful; in some instances, theories may become self-fulfilling (Ferraro, Pfeffer, & Sutton, 2009). In their commentary about why theories matter, Fabrizio Ferraro et al. cited the work of Carol Dweck (2006), who showed that people’s beliefs about intelligence (whether fixed vs. mutable/changeable) can shape their behavior. In particular, those who believed that intelligence was fixed behaved differently (e.g., avoided tasks where they thought they would fail) than did those who believed that intelligence was mutable. Dweck’s research also showed that these beliefs about intelligence can be changed through social influence. In every situation, we need to ask research questions about the tenets or principles that theories propose.

**MAKING A CONNECTION BETWEEN A THEORY AND A GOOD RESEARCH QUESTION**

Often the way research questions are posed limits their scope and potential generalizability; that is, questions are asked in a way that limits them to a particular situation. As an example, you might be interested in the size of artwork displayed in a doctor’s waiting room and the effect of that displayed artwork on patients’ satisfaction with their time spent in the waiting room. Notice that the statement did not say patients’ satisfaction with the entire visit. Here is an important observation. When we think about variables we might manipulate or vary, such as the size of artwork, and the outcomes that might be affected, we need to think about the “distance” between these manipulated variables (such as artwork) and the outcome variables (such as satisfaction). Why would we expect the size of artwork in the *waiting room* to affect satisfaction with the entire visit? Wouldn’t we want to limit our test to a more reasonable relationship—satisfaction with the time spent in the waiting room?

Now when we return to the idea of the size of the artwork, we need to pose this question in a way that avoids a restrictive and narrow focus. If we try to answer this question only for one particular size of art at two different distances, won’t we have to repeat the study with many other sizes and distances? Thus, it would help to see our research question in terms of a larger framework, something like the psychophysics of size, where we could answer the question in terms of the ratio of the size of the art displayed relative to the viewing distance in terms of the effect on satisfaction. For an example of this
The Research Experience

kind of study, see the work of Jack Nasar and Arthur Stamps (2009) on what are called infill McMansions (“too big” houses constructed in existing smaller scale neighborhoods). Basing their research on the Weber–Fechner law (proposing a relationship between the magnitude of a physical stimulus and the intensity of people’s responses), Nasar and Stamps showed that what bothers people is not the actual size of the infill house but the relative size of the house (i.e., how the house fits into the neighborhood). Furthermore, in terms of style, large discrepancies in the height of the infill houses relative to neighbors’ houses were more disliked than were large discrepancies in width. This study uses computer-generated houses as stimuli (a very effective means of experimental control) and demonstrates how the order of presentation can be counterbalanced (Chapter 8) to make sure it is the stimuli themselves, and not the order in which they are seen, that influences our responses. In our example of the research on size and distance of art, we would need to test our hypothesis with carefully selected sizes and distances, following the Weber–Fechner law, to reach a conclusion about the ratio of size to distance that produces the most positive outcome. We want to take a specific research question and ask it in a way that has more generalizability (i.e., greater reach)—but not so much that we wouldn’t expect to see any impact (see Chapter 2 for more discussion of the research “gap”).

**REVISIT AND RESPOND**

At this point, you should be able to:

- Explain the value of commonsense in posing research questions
- Explain the difference between a law, a theory, and a hypothesis
- Describe what makes something a good research question

**Summary**

We have considered in depth the qualities of thinking that both may help (schema development; commonsense) and hurt (stereotypes; heuristics) our approach to the research process. You have observed the kinds of cognitive shortcuts or heuristics that characterize some decision-making situations and can recognize when those biases may come into play. Exposure to Shermer’s (1997) list of how thinking goes wrong should have made you more attentive to the decisions you will make in your own research. But as researchers likely at the start of your investigative career, you are in a good position to think innovatively because you are less likely than some of your professors to be constrained by a particular way of doing research. You understand the different levels of predictability and generalizability related to laws, theories, and hypotheses. You are ready to begin your journey to combine tradition and innovation.
If you have not had time to consider them earlier, here is the list of REVISIT and RESPOND questions from this chapter.

- Explain what it means to say humans are limited information processors
- Describe the concept of a schema and its adaptive and maladaptive implications for research
- Define heuristics and give examples of representativeness and availability
- Explain the Wason Selection Task and what it shows about the difference between confirming and disconfirming hypotheses
- Give an example from each one of Shermer’s (1997) categories:
  - Problems in scientific thinking
  - Problems in pseudoscientific thinking
  - Logical problems in thinking
  - Psychological problems in thinking
- Explain why science is a combination of tradition and innovation
- Explain the value of commonsense in posing research questions
- Explain the difference between a law, a theory, and a hypothesis
- Describe what makes something a good research question

**BUILD YOUR SKILLS**

1. Think of a situation in your life where you reached an incorrect conclusion, and explain how “your thinking went wrong.”

2. *The Atlantic* is a monthly magazine that has a section called “Study of Studies” featuring research findings. Locate the magazine online and the “Study of Studies” section for April 2016. For that month, the focus is “Brag better: How to boast without seeming to.” From the descriptions, select a study you think falls into the category of “commonsense” and one that does not. Explain your answers.

**SAGE edge**
